Abstract

Many existing rule learning systems are computationally expensive on large noisy datasets. In this paper we evaluate the recently-proposed rule learning algorithm IREP on a large and diverse collection of benchmark problems. We show that while IREP is extremely efficient, it frequently gives error rates higher than those of C4.5 and C4.5rules. We then propose a number of modifications resulting in an algorithm RIPPERk that is very competitive with C4.5rules with respect to error rates, but much more efficient on large samples. RIPPERk obtains error rates lower than or equivalent to C4.5rules on 22 of 37 benchmark problems, scales nearly linearly with the number of training examples, and can efficiently process noisy datasets containing hundreds of thousands of examples.

2 PREVIOUS WORK

2.1 COMPLEXITY OF RULE PRUNING

Many of the techniques used in modern rule learners have been adapted from decision tree learning. Most widely-used decision tree learning systems use an overfit-and-simplify learning strategy to handle noisy data; a hypothesis is formed by first growing a complex tree which “overfits” the data, and then simplifying or pruning the complex tree [Quinlan, 1987; Mingers, 1986]. Usually (but not always) such pruning strategies improve error rates on unseen data when the training data is noisy [Quinlan, 1987; Mingers, 1989; Schaffer, 1992]. A variety of methods have been proposed to prune trees, but one effective technique is reduced error pruning (REP). REP can be easily adapted to rule learning systems [Pagallo and Haussler, 1990; Brunk and Pazzani, 1991].

In REP for rules, the training data is split into a growing set and a pruning set. First, an initial rule set is formed that overfits the growing set, using some heuristic method. This overlarge rule set is then repeatedly simplified by applying one of a set of pruning operators; typical pruning operators would be to delete any single condition or any single rule. At each stage of simplification, the pruning operator chosen is the one that yields the greatest reduction of error on the
pruning set. Simplification ends when applying any pruning operator would increase error on the pruning set.

REP for rules usually does improve generalization performance on noisy data [P갈로 and Haussler, 1990; Brunk and Pazzani, 1991; Weiss and Indurkhya, 1991; Cohen, 1993; Fürnkranz and Widmer, 1994]; however, it is computationally expensive for large datasets. In previous work [Cohen, 1993] we showed that REP requires $O(n^4)$ time, given sufficiently noisy data; in fact, even the initial phase of overfitting the training data requires $O(n^2)$ time. We then proposed an alternative overfit-and-simplify method called Grow that is competitive with REP with respect to error rates, and was an order of magnitude faster on a set of benchmark problems.

We also showed that Grow was asymptotically faster than REP on random data—if one assumes that Grow's hypothesis is approximately the same size as the target concept. However, Cameron-Jones [1994] later showed that Grow systematically overfits the target concept on noisy data. This has an adverse effect on Grow's time complexity and as a result Grow also requires $O(n^4)$ time asymptotically.

In another response to the inefficiency of REP, Fürnkranz and Widmer [1994] proposed a novel learning algorithm called incremental reduced error pruning (IREP). IREP was shown experimentally to be competitive with both REP and Grow with respect to error rates, and much faster than either; in fact, on 18 of 20 benchmark problems, IREP was faster than the initial step of overfitting the data.

In this paper, we will take as our point of departure the promising results obtained by Fürnkranz and Widmer with the IREP algorithm. Our initial goal was simply to replicate their results, to evaluate IREP on a broader set of benchmarks, and to compare IREP to more mature tree and rule induction methods. In the course of doing this, we discovered that IREP's generalization performance could be considerably improved, without greatly affecting its computational efficiency. In the remainder of the paper we will describe our implementation of the original IREP algorithm, and give evidence that it affords room for improvement. We will then outline three modifications: a new metric for guiding its pruning phase, a new stopping condition, and a technique for "optimizing" the rules learned by IREP. Taken together these modifications give generalization performance that is comparable to C4.5 and C4.5rules [Quinlan, 1994] on a large set of diverse benchmarks. The modified learning algorithm, however, still scales well with the number of training examples. The current implementation can efficiently handle training sets of several hundred thousand examples.

2.2 INCREMENTAL REDUCED ERROR PRUNING

The IREP rule-learning algorithm is described in detail by Fürnkranz and Widmer [1994], but we will summarize it below. IREP tightly integrates reduced error pruning with a separate-and-conquer rule learning algorithm. Figure 1 presents a two-class version of this algorithm. (In the two-class Boolean case a "rule" is simply a conjunction of features, and a "rule set" is a DNF formula.) Like a standard separate-and-conquer algorithm, IREP builds up a rule set in a greedy fashion, one rule at a time. After a rule is found, all examples covered by the rule (both positive and negative) are deleted. This process is repeated until there are no positive examples, or until the rule found by IREP has an unacceptably large error rate.

In order to build a rule, IREP uses the following strategy. First, the uncovered examples are randomly partitioned into two subsets, a growing set and a pruning set. In our implementation, the growing set contains 2/3 of the examples.

Next, a rule is "grown". Our implementation of GrowRule is a propositional version of FOIL [Quinlan,
1990; Quinlan and Cameron-Jones, 1993). It begins with an empty conjunction of conditions, and considers adding to this any condition of the form \( A_v = v,\ A_v \leq \theta, \) or \( A_v \geq \theta, \) where \( A_v \) is a nominal attribute and \( v \) is a legal value for \( A_v, \) or \( A_v \) is a continuous variable and \( \theta \) is some value for \( A_v \) that occurs in the training data. GrowRule repeatedly adds the condition that maximizes FOIL's information gain criterion until the rule covers no negative examples from the growing dataset.

After growing a rule, the rule is immediately pruned. To prune a rule, our implementation considers deleting any final sequence of conditions from the rule, and chooses the deletion that maximizes the function

\[
v(Rule, PrunePos, PruneNeg) \equiv \frac{p + (N - n)}{P + N}\]

where \( p \) (respectively \( N \)) is the total number of examples in \( PrunePos \) (\( PruneNeg \)) and \( n \) is the number of examples in \( PrunePos \) (\( PruneNeg \)) covered by \( Rule.\) This process is repeated until no deletion improves the value of \( v.\)

The IREP algorithm described above is for two-class learning problems. Our implementation handles multiple classes as follows. First, the classes are ordered. In the experiments described below the ordering is always in increasing order of prevalence, i.e., the ordering is \( C_1, \ldots, C_k \) where \( C_1 \) is the least prevalent class and \( C_k \) is the most prevalent. Then, IREP is used to find a rule set that separates \( C_1 \) from the remaining classes; this is done with a single call to IREP where \( PosData \) contains the examples labeled \( C_1 \) and \( NegData \) contains the examples labeled \( C_2, \ldots, \) or \( C_k.\) Next, all instances covered by the learned rule set are removed from the dataset, and IREP is used to separate \( C_2 \) from classes \( C_3, \ldots, C_k.\) This process is repeated until a single class \( C_k \) remains; this class will be used as the default class.

We also extended the rule learning algorithm to handle missing attributes as follows: all tests involving the attribute \( A \) are defined to fail on instances for which the value of \( A \) is missing. This encourages the learner to separate out the positive examples using tests that are known to succeed.

2.3 DIFFERENCES FROM FÜRKNKRANZ AND WIDMER'S IREP

This implementation differs from Fürnkranz and Widmer's in several details. In pruning rules, our implementation allows deletions of any final sequence of conditions, whereas Fürnkranz and Widmer's implementation allows only deletions of a single final condition. Our implementation also stops adding rules to a rule set when a rule is learned that has error rate greater than 50\%, whereas Fürnkranz and Widmer's implementation stops when the accuracy of the rule is less than the accuracy of the empty rule.\(^3\)

More importantly, our implementation supports missing attributes, numerical variables and multiple classes. This makes it applicable to a wider range of benchmark problems.

3 EXPERIMENTS WITH IREP

Experiments with IREP showed that it is indeed fast. Results for one representative artificial problem\(^2\) are summarized in the first graph in Figure 2; the CPU time needed by C4.5rules is also shown.\(^3\) The results are shown on a log-log scale; recall that polynomials appear as lines on such a plot, with the slope of the line indicating its degree. \( \text{C4.5rules} \) scales roughly as the cube of the number of examples, whereas IREP scales almost linearly. Extrapolating the curves suggests that it would require about 75 CPU years for \( \text{C4.5rules} \) to process the 500,000 example dataset, which IREP handles in around seven CPU minutes.

Although we have used an artificial concept with an extremely large number of training examples to demonstrate these issues, similar performance issues also arise on natural datasets, as the two smaller graphs of Figure 2 demonstrate.

For reference, the first graph in Figure 2 also shows the curves \( k a^x \) and \( y = k a \log^2 x.\) Fürnkranz and Widmer's formal analysis of IREP predicts a running time of \( O(m \log^2 m) \), where \( m \) is the number of examples, on

\(^1\)Actually, Fürnkranz and Widmer described two pruning algorithms. The first, which they called IREP, prunes according to Equation 1, and stops when \( p/(p + n) < N/(P + N). \) The second, which they called IREP2, prunes according to the metric \( v(Rule, PrunePos, PruneNeg) \equiv \frac{p}{P} \) and stops when \( p/(p + n) < 1/2. \) Our experiments confirmed the conclusion of Fürnkranz and Widmer that IREP generally outperforms IREP2; however, we also discovered that IREP's performance was noticeably improved by adopting IREP2's stopping condition.

\(^2\)The concept \( ab \lor bcd \lor defg \) with 12 irrelevant binary attributes, 20\% classification noise, and uniformly distributed examples. CPU time was measured on a MIPS irix 5, configured with 8 133 MHz R-4400 processors and 1 GB of memory. Since IREP is a randomized algorithm (because of its random partitioning of the examples) the curve for IREP is the average of 10 trials.

\(^3\)The time for \( \text{C4.5rules} \) ignores the time needed to run C4.5. However, C4.5 is generally much faster than \( \text{C4.5rules} \) on this problem, \( \text{C4.5} \) requires less than 400 CPU seconds to handle the 500,000 example dataset. The run-time of \( \text{C4.5} \) is generally comparable to that of IREP.
any dataset that contains a fixed percentage of classification noise. Our results are consistent with this prediction. Analysis similar to Fürnkranz and Widmer’s also predicts the cubic behavior shown by C4.5rules.

Although IREP is efficient, experiments on real-world datasets showed that the generalization performance of IREP offered substantial room for improvement. We compared IREP to C4.5 and C4.5rules on a diverse set of benchmark problems, summarized in Table 1. Where a test set associated with the benchmark is indicated, we ran C4.5 and C4.5rules once, and ran IREP 10 times and averaged. Where no test set is indicated, we ran 10 different 10-fold cross-validations for all the algorithms and averaged the results. Due to space considerations we will focus on comparisons to C4.5rules, since it also learns rule sets; however, the performance of C4.5 and C4.5rules on these datasets was similar.

We used C4.5 Release 6 [Quinlan, 1994], and the most recent version of C4.5rules [Quinlan, 1993].

The left-hand graph of Figure 3 contains one point for each benchmark problem, positioned so that IREP’s error rate is the x-axis position and C4.5rules’ error rate is the y-axis position. Thus for points below the line \( y = x \), IREP’s performance is inferior to C4.5rules, and for points above the line IREP’s performance is better. From the graph one can readily see that IREP does worse than C4.5rules more often than it does better; specifically, IREP’s error rate is higher 23 times, lower 11 times, and the same 3 times.

Of course, it may be that IREP is in fact as likely to outperform C4.5rules as the converse on problems from this test suite, and that the won-lost-tie ratio of 11-23-3 is due to random variation in the error esti-
mates. Using a nonparametric sign test [Mendenhall et al., 1981, page 578], one can determine that the probability of observing a ratio this one-sided would be just under 0.05 if IREP had a 50/50 chance of bettering C4.5rules on problems in this test suite. We can thus conclude with 95% confidence that C4.5rules outperforms IREP on this test suite.4

It is also evident from the graph that IREP seldom does much better than C4.5rules, and not infrequently does much worse. It is not obvious how to best aggregate measurements across learning problems, but one method is to consider the average value of the ratio

\[
\text{error rate of IREP} / \text{error rate of C4.5rules}
\]

For this set of problems the average of this ratio is 1.13, if one discounts a single extreme outlier; thus on average IREP’s error rates are about 13% higher than those of C4.5rules. (This average is 1.52 if one includes the mushroom dataset—on this benchmark C4.5rules obtains an error of 0.2% to IREP’s 3.1%.)

As an additional point of reference, we also ran propositional FOIL without any pruning mechanism. The ratio of the error rate of the hypothesis obtained by “overfitting” the data with propositional FOIL to the error rate of C4.5rules is 1.17 excluding the mushroom dataset, and 1.14 overall. Finally, we ran IREP2 (also described by Flunkranz and Widmer [1994]) and IREP with Fünkranz and Widmer’s stopping condition. The average ratio for IREP2 was 1.15 without the mushroom dataset, and 1.14 overall. For IREP with the more restrictive Fünkranz and Widmer stopping condition, the average ratio was 1.71 without mushroom and 2.08 overall. The best non-loss-tied record of any of these three systems relative to C4.5rules was 17-20-0, achieved by propositional FOIL without pruning. To summarize, on average, all of the IREP variants performed substantially worse than C4.5rules, and none of the IREP variants performed substantially better than simply overfitting the data.

There is also evidence that IREP fails to converge on some natural datasets. One example is the well-known KRK-illegal problem [Muggleton et al., 1989;
Quinlan, 1990]. We encoded a propositional version of this problem, and implemented a data generator.\textsuperscript{5} Without noise, IREP reliably learns an approximate theory with an error rate of 0.6% from as few as 100 examples; however, IREP does not improve this error rate even if as many as 100,000 examples are given. In contrast C4.5rules reliably produces a perfect theory from only 5000 examples. Artificial examples can also be constructed which show non-convergence to a greater extent; for example, IREP obtains an error of 9.5% given anywhere between 100 and 100,000 noise-free examples of the concept \(ab \lor ac \lor ade\). This is worrisome behavior for an algorithm whose main strength is that it efficiently handles very large numbers of examples.

4 IMPROVEMENTS TO IREP

Based on our experiments with IREP, we implemented three modifications to the algorithm: an alternative metric for assessing the value of rules in the pruning phase of IREP; a new heuristic for determining when to stop adding rules to a rule set; and a postpass that "optimizes" a rule set in an attempt to more closely approximate conventional (i.e., non-incremental) reduced error pruning.

4.1 THE RULE-VALUE METRIC

The occasional failure of IREP to converge as the number of examples increases can be readily traced to the metric used to guide pruning (given above in Equation 1). The preferences encoded in this metric are sometimes highly unintuitive; for instance (assuming that \(P\) and \(N\) are fixed) the metric prefers a rule \(R_1\) that covers \(p_1 = 2000\) positive examples and \(n_1 = 1000\) negative examples to a rule \(R_2\) that covers \(p_2 = 1000\) examples and \(n_2 = 1\) negative example; note, however, that \(R_2\) is highly predictive and \(R_1\) is not. We thus replaced IREP's metric with

\[
v^*(\text{Rule, PrunePos, PruneNeg}) \equiv \frac{p-n}{p+n}
\]

which seems to have more intuitively satisfying behavior.

4.2 THE STOPPING CONDITION

Our implementation of IREP stops greedily adding rules to a rule set when the last rule constructed has an error exceeding 50% on the pruning data. This heuristic often stops too soon given moderate-sized samples; this is especially true when learning a concept containing many low-coverage rules. Our assessment of the problem is that for low-coverage rules, the estimate of error afforded by the pruning data has high variance; thus in learning a series of small rules, there is a good chance that one of the rules in the series will have its error rate incorrectly assessed at more than 50%, causing IREP to stop prematurely. Put another way, IREP seemed to be unduly sensitive to the "small disjunct problem" [Holte et al., 1989].

Our solution to this problem is the following. After each rule is added, the total description length of the rule set and the examples is computed. The new version of IREP stops adding rules when this description length is more than \(d\) bits larger than the smallest de-
scription length obtained so far, or when there are no more positive examples. In the experiments of this paper we used $d = 64$. The rule set is then simplified by examining each rule in turn (starting with the last rule added) and deleting rules so as to reduce total description length.\footnote{To briefly summarize our MDL encoding scheme: the method used for encoding a set of examples given a theory is the same as that used in the latest version of C4.5rules [Quinlan, 1995]. One part of this encoding scheme allows one to identify a subset of $k$ elements of a known set of $n$ elements using \[ S(n, k, p) = k \log_2 \frac{1}{p} + (n - k) \log_2 \frac{1}{1 - p} \] bits, where $p$ is known by the recipient of the message. Thus we allow $[\log_2 k] + S(n, k, k/n)$ bits to send a rule with $k$ conditions, where $n$ is the number of possible conditions that could appear in a rule and $[\log_2 k]$ is the number of bits needed to send the integer $k$. As in C4.5rules [Quinlan, 1994, page 53] the estimated number of bits required to send the theory is multiplied by 0.5 to adjust for possible redundancy in the attributes.}

Together, the revised rule-value metric and stopping heuristic substantially improve IREP's generalization performance. Unlike the original IREP, the modified version of IREP (henceforth IREP*) converges $KR$-illegal and the artificial concept $abv/acv$ade, IREP*’s won-lost-tied record against IREP is 28-8-1; thus with high confidence ($p > 0.002$) one can state that IREP* outperforms IREP on problems from this test suite. The error ratio to C4.5rules is also reduced from 1.13 (or 1.52, including $mushroom$) to 1.06 (or 1.04, including $mushroom$*). IREP*’s won-lost-tied record against C4.5rules is 16-21-0.

### 4.3 RULE OPTIMIZATION

The repeated grow-and-simplify approach used in IREP can produce results quite different from conventional (non-incremental) reduced error pruning. One way to possibly improve IREP*’s incremental approach is to postprocess the rules produced by IREP* so as to more closely approximate the effect of conventional reduced error pruning. For instance, one could re-prune each rule so as to minimize the error of the complete rule set.

After some experimentation we developed the following method for “optimizing” a rule set $R_1, \ldots, R_k$. Each rule is considered in turn: first $R_1$, then $R_2$, etc., in the order in which they were learned. For each rule $R_i$, two alternative rules are constructed. The replacement for $R_i$ is formed by growing and then pruning a rule $R'_i$, where pruning is guided so as to minimize error of the entire rule set $R_1, \ldots, R_i, \ldots, R_k$ on the pruning data. The revision of $R_i$ is formed analogously, except that the revision is grown by greedily adding conditions to $R_i$, rather than the empty rule. Finally a decision is made as to whether the final theory should include the revised rule, the replacement rule, or the original rule. This decision is made using the MDL heuristic.\footnote{Using Pflunkranz and Widmer's stopping criterion.} Optimization is integrated with IREP* as follows: First, IREP* is used to obtain an initial rule set. This rule set is next optimized as described above. Finally rules are added to cover any remaining positive examples using IREP*. Below, we will call this algorithm RIPPER (for Repeated Incremental Pruning to Produce Error Reduction.).

Optimization can also be iterated by optimizing the rule set output by RIPPER and then adding additional rules using IREP*; we will call this algorithm RIPPER2, and in general use RIPPER$k$ for the algorithm that repeatedly optimizes $k$ times.

### 4.4 GENERALIZATION PERFORMANCE

RIPPER noticeably improves generalization performance over IREP*. Its won-lost-tied record against IREP* is 28-7-2, a significant improvement ($p > 0.008$). The error ratio to C4.5rules is also reduced: excluding $mushroom$, the error ratio is 1.06 for IREP* and 1.01 for RIPPER, and including $mushroom$, the error ratio is 1.04 for IREP* and 0.982 for RIPPER. RIPPER’s won-lost-tied record against C4.5rules is 20-15-2.

One additional stage of optimization gives some fur-

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|c|}
\hline
& \multicolumn{2}{c|}{won-lost-tied} & \multicolumn{2}{c|}{error ratio} \\
\cline{2-5}
& vs C4.5rules & to C4.5rules & vs C4.5rules & to C4.5rules \hline
IREP* & 9-28-0 & 2.08 & 1.71 & 1.93 \hline
IREP2 & 11-25-1 & 1.15 & 1.15 & 2.22 \hline
IREP & 11-23-3 & 1.51 & 1.13 & 1.20 \hline
IREP* & 16-21-0 & 1.04 & 1.06 & 1.09 \hline
RIPPER & 20-15-2 & 0.98 & 1.01 & 1.03 \hline
RIPPER2 & 21-15-1 & 0.97 & 0.99 & 1.01 \hline
\end{tabular}
\caption{Summary of generalization results}
\end{table}
ther benefit. RIPPER2 reduces the error ratio to C4.5rules to 0.995 excluding mushroom, or 0.958 including mushroom, and RIPPER2’s won-lost-tied against C4.5rules is improved to 21-15-2. RIPPER2 is not statistically significantly better than C4.5rules; however, RIPPER2 is certainly quite competitive on the problems in this test suite. To make this concrete, let q be the probability that RIPPER2’s measured error rate will be less than or equal to that of C4.5rules on a problem taken at random from the test suite. The won-lost-tied record of 21-15-2 means we can be 93% confident that q is at least 0.5, 95% confident that q is at least 0.488, and 99% confident that q is at least 0.431.

The right-hand graph in Figure 3 gives a more detailed comparison of the error rates of RIPPER2 and C4.5rules, and Table 2 summarizes some of the generalization results given in this section.

One problem with averaging error ratios is that when the actual error rates are very small, ratios tend to have extreme values. (This is the reason why we have reported all averages with and without the mushroom dataset: for this dataset the actual error rates range from 0.0% to 3.1% and the ratios range from 0.0 to 17.5.) The following remarks may help reassure readers of the stability of our comparison:

- If groups of similar datasets are weighted together, then the average ratio of RIPPER2 to C4.5rules is 0.997. If mushroom is excluded, then the weighted average ratio is 1.005.
- If the two largest and the two smallest ratios are excluded, then the average ratio of RIPPER2 to C4.5rules is 0.986. (The ratio for mushroom is one of the four extreme values.)
- The average difference between RIPPER2’s error rate and C4.5rules’ error rate is 0.1%.
- The won-lost-tied record of RIPPER2 to the C4.5 decision tree learner (with pruning) is 23-12-2.

4.5 EFFICIENCY OF RIPPERk

Importantly, none of the modifications we have described have a major effect on computational efficiency. Figure 2 also shows how RIPPER2 scales with the number of examples on three concepts: one artificial concept, and two of the larger and noisier natural datasets in our test suite. The fact that the lines for RIPPER2 and IREP are parallel shows that the modifications we have introduced affect only the constant factors, and not the asymptotic complexity of the algorithm. The constant factors for RIPPER2 are also still reasonably low: RIPPER2 requires only 61 CPU minutes to process 500,000 examples of the artificial concept of Figure 2. RIPPERk is also quite space efficient, as it requires no data structures larger than the dataset.

In previous work [Cohen, 1993] we sought formal explanations for the efficiency or inefficiencies of REP and other rule-pruning algorithms. While space does not permit such an analysis here, we would like to present some of the intuitions as to why RIPPERk is so much faster on large noisy datasets.

The basic strategy used by RIPPERk to find a ruleset that models the data is to first use IREP* to find an initial model, and then to iteratively improve that model, using the “optimization” procedure described in 4.3. This process is efficient because building the initial model is efficient, because the initial model does not tend to be large relative to the target concept, and because the optimization steps only require time linear in the number of examples and the size of the initial model.

C4.5rules also constructs an initial model and then iteratively improves it. However, for C4.5rules, the initial model is a subset of rules extracted from a unpruned decision tree, and the improvement process greedily deletes or adds single rules in an effort to reduce description length. C4.5rules repeats this process for several different-sized subsets of the total pool of extracted rules and uses the best ruleset found as its hypothesis; the subsets it uses are the empty ruleset, the complete ruleset, and randomly-chosen subsets of 10%, 20%, . . . , and 90% of the rules.

Unfortunately, for noisy datasets, the number of rules extracted from the unpruned decision tree grows as m, the number of examples. This means that each initial model (save the empty model) will also be of size proportional to m, and hence if m is sufficiently large, all of the initial models will be much larger than the target hypothesis. This means that to build a theory about the same size as the target concept always requires many (on the order of m) changes to the initial model, and at each step in the optimization, many (on the order of m) changes are possible. The improvement process is thus expensive; since it is a greedy search, it is also potentially quite likely to miss finding
the best ruleset.\footnote{This situation should be contrasted to decision tree pruning, in which even a large tree can be pruned efficiently and, in certain senses, optimally; for instance, the pruned tree with the lowest error on a pruning set can be found in linear time.}

In summary, both RIPPER$k$ and C4.5rules start with an initial model and iteratively improve it using heuristic techniques. However, for large noisy datasets, RIPPER$k$ generally seems to start with an initial model that is about the right size, while C4.5rules starts with an over-large initial model. This means that RIPPER$k$'s search is more efficient. We conjecture also that RIPPER$k$'s search is also more effective on large noisy datasets. (RIPPER2 generally seems to do better compared to C4.5rules on larger datasets; in particular for datasets with no more than 150 examples, the average ratio of RIPPER2 to C4.5rules is 1.051, and for datasets with more than 150 examples, the average ratio of RIPPER2 to C4.5rules is 0.944.)

5 CONCLUSIONS

\textit{Incremental reduced error pruning} (IREP) is a recent rule learning algorithm that can efficiently handle large noisy datasets. In this paper we have presented some experiments on a large collection of benchmark problems with an extended implementation of IREP which allows continuous variables and multiple classes. We showed that IREP does not perform as well as the more mature (but also more expensive) rule learning algorithm C4.5rules.

We also proposed a series of improvements to IREP that make it extremely competitive with C4.5rules, without seriously affecting its efficiency. IREP$*$ incorporates a new metric to guide rule pruning and an MDL-based heuristic for determining how many rules should be learned. RIPPER$k$ adds to this $k$ iterations of an optimization step that more closely mimics the effect of non-incremental reduced error pruning.

IREP$*$ and RIPPER$k$ were shown statistically to be clear improvements over IREP on problems from our test suite. RIPPER2 is also extremely competitive with C4.5rules; in fact on 22 of 37 problems in the test suite RIPPER2 achieves error rates lower than or equivalent to those of C4.5rules.

However, on noisy datasets, RIPPER$k$ is much more efficient than C4.5rules. It scales nearly linearly with the number of examples in a dataset; in contrast C4.5rules scales as the cube of the number of examples. This asymptotic improvement translates to speedups of several orders of magnitude on problems of modest size (up to a few thousand examples), and the ability to effectively process datasets containing several hundreds of thousands of noisy examples.

Acknowledgements

Much of this research was conducted during a visit to the University of Sydney, which was funded by a grant to Ross Quinlan from the Australian Research Council. This research and this paper have benefitted substantially from numerous helpful discussions with Ross Quinlan, Nitin Indurkhya, and other members of University of Sydney machine learning community. The author is also grateful for valuable suggestions from Jason Cadlett, for comments from Jason Cadlett and Haym Hirsh on a draft of the paper, and for the suggestions made by two anonymous reviewers.
